Received 28 January 2009/Returned for modification 3 March 2009/Accepted 31 March 2009

***Escherichia coli* clonal group A (CGA) commonly exhibits a distinctive multidrug antimicrobial resistance phenotype—i.e., resistance to ampicillin, chloramphenicol, streptomycin, sulfonamides, tetracycline, and trimethoprim (ACSSuTTP)—and has accounted for up to 50% of trimethoprim-sulfamethoxazole-resistant *E. coli* urinary tract infections in some locales. Annotation of the whole-genome sequencing of UMN026, a reference CGA strain, clarified the genetic basis for this strain's ACSSuTTP antimicrobial resistance phenotype. Most of the responsible genes were clustered in a unique 23-kbp chromosomal region, designated the genomic resistance module (GRM), which occurred within a 105-kbp genomic island situated at the *leuX* tRNA. The GRM is characterized by numerous remnants of mobilization and rearrangement events suggesting multiple horizontal transfers. Additionally, comparative genomic analysis of the *leuX* tRNA genomic island in 14 sequenced *E. coli* genomes showed that this region is a hot spot of integration, with the presence/absence of specific subregions being uncorrelated with either the phylogenetic group or the pathotype. Our data illustrate the importance of whole-genome sequencing in the detection of genetic elements involved in antimicrobial resistance. Additionally, this is the first documentation of the *bla*<sub>TEM</sub> and *dhfr*<sub>VII</sub> genes in a chromosomal location in *E. coli* strains.**

Emerging antimicrobial resistance among uropathogens increases the complexity of management for acute uncomplicated cystitis. The recently described *Escherichia coli* clonal group A (CGA) causes infections of the urinary tract and other extraintestinal sites in diverse host populations. CGA is associated with trimethoprim-sulfamethoxazole resistance and, although most highly prevalent in the United States, exhibits a worldwide distribution (6, 7, 12, 13). This clonal group has accounted for up to 50% of trimethoprim-sulfamethoxazole-resistant urinary tract infections (UTIs) due to *E. coli* in some U.S. locales (13), illustrating the importance of the dissemination of this clone.

Although CGA belongs to phylogenetic group D, which overall is less closely associated with extraintestinal virulence than group B2, CGA exhibits typical extraintestinal virulence traits (the F16 *papA* allele, *papG* allele II, *iutA*, *kpsMII*, *traT*, and *ompT*) and can be as pathogenic as classic group B2 strains in a mouse UTI model (7). Many CGA strains exhibit distinc-

tive O antigens (O11, O17, O73, and O77) and a distinctive multidrug antimicrobial resistance phenotype: resistance to ampicillin, chloramphenicol, streptomycin, sulfonamides, tetracycline, and trimethoprim (i.e., ACSSuTTP) (6, 13). The finding of highly similar or indistinguishable pulsed-field gel electrophoresis profiles among isolates from multiple locations in the United States suggests a recent dissemination of CGA (13). This expansion may have been due to the combination of CGA's virulence potential and its antimicrobial resistance capabilities, in contrast to the historically noted negative association between resistance and virulence in *E. coli* (1, 5, 11).

Using an approach of whole-genome sequencing and comparative genomic analysis, the goals of this study were (i) to identify the genetic basis for the antimicrobial resistance of a representative CGA strain and (ii) to understand the evolutionary history of these genetic determinants.

## MATERIALS AND METHODS

**Bacterial strain.** Strain UMN026 is a CGA urine isolate from a woman with acute cystitis at the University of Minnesota Student Health Service in the late 1990s (8, 15). Consistent with its CGA background, UMN026 exhibits the O17 O antigen, a typical CGA-associated virulence gene profile that includes *pap* (P fimbriae, with the F16 *papA* variant and *papG* allele II), *iutA* (aerobactin receptor), and *kpsMII* (group 2 capsule), and the ACSSuTTP antimicrobial resistance profile.

<sup>∇</sup> Published ahead of print on 13 April 2009.

**Sequencing of the *E. coli* UMN026 genome.** The UMN026 genome was sequenced as part of a whole-genome sequencing project (ColiScope; [www.genoscope.cns.fr](http://www.genoscope.cns.fr)) at the Genoscope Sequencing Center (Evry, France) (16). Sequencing and assembly of the UMN026 genome were performed as follows. The complete genome sequence of *E. coli* UMN026 was determined using the whole-genome shotgun method (10× coverage). Three libraries were made. Two plasmid libraries of 3 kbp and 10 kbp, obtained by mechanical shearing, were constructed in plasmid pCNA2.1 (Invitrogen) and in home vector pCNS (pSU18 modified), respectively. One bacterial artificial chromosome library with an average insert size of 30 kbp was constructed by enzymatic digestion (HindIII) and ligation into pBeloBacII (CalTech). The Phred/Phrap/Consed software package ([www.phrap.com](http://www.phrap.com)) was used for sequence assembly and quality assessment. To resolve contigs, sequence finishing was performed by PCR amplification, primer walking, and/or transposition.

**Annotation of the *E. coli* UMN026 genome.** The MaGe (Magnifying Genome) software program (17) was used for gene annotation and comparative analysis of the UMN026 genome. Using the AMiGene (annotation of microbial genes) (17) program, open reading frames (ORFs) were predicted (assigned a unique identifier prefixed with ECUMN\_) and submitted to automatic functional annotation, including gene order conservation analysis (i.e., assessment of conservation of the chromosomal colocalization between pairs of orthologous genes from different genomes). Manual validation of the automatic annotation was performed only on the UMN026 genes/regions without orthologues in the *E. coli* K-12 genome, with the help of the MaGe interface, which allows graphic visualization of the annotations, enhanced by a synchronized representation of synteny groups in other genomes chosen for comparisons (17). Sequence data for comparative analyses were obtained from the NCBI databases (<ftp://ftp.ncbi.nlm.nih.gov>). Annotations of the chromosomal genomic resistance module (GRM [see below]) gene cluster described in this paper range from ECUMN\_4803 (*intB*) to ECUMN\_4832 (a transposase gene fragment) and are available in public databanks (accession no. CU928163).

**Identification of subregions (modules) within the *leuX* tRNA genomic islands.** The genomic islands located at the *leuX* tRNA were defined using the synteny breaks between 14 *E. coli* strains. Of these, 10 were pathogenic strains, including UMN026 and IAI39 (two extraintestinal pathogenic group D strains), E2348/69 (an enteropathogenic group B2 strain), S88, APECO1, CFT073, UTI89, and 536 (five extraintestinal pathogenic group B2 strains), 042 (an enteroaggregative group D strain), O157:H7 Sakai (an enterohemorrhagic group E strain), and 55989 (an enteroaggregative group B1 strain), whereas 4 were commensal strains, including ED1a (a group B2 strain), IAI1 (a group B1 strain), and K-12 and HS (two group A strains). It appeared that these genomic islands have a composite structure: e.g., they are made up of regions that are partially conserved but are found in different synteny groups (i.e., in different genomic locations) in the different *E. coli* strains. Thus, the predicted genomic islands were manually divided into subregions (or modules) which are found in only a subset of the compared *E. coli* strains.

## RESULTS AND DISCUSSION

The UMN026 genome includes a chromosome of 5,202,090 bp with 5,086 ORFs, plus two plasmids, p1ECUMN, comprising 122,301 bp for 157 ORFs, and p2ECUMN comprising 33,809 bp for 49 ORFs (16). All but one of the resistance genes corresponding to the strain's characteristic ACSSuTTp phenotype were identified within a single chromosomal region. The sole exception, resistance to tetracycline, was attributable to both the *mar* operon, located on the chromosome at bp 1,827,757 (origin upstream of *thrA*), which enhances impermeability to tetracycline, and the *tet* operon, located on plasmid p1ECUMN, which encodes an efflux pump (see Table S1 in the supplemental material). In contrast, all of the remaining resistance genes, i.e., those coding for resistance to chloramphenicol, trimethoprim, streptomycin, sulfonamides, and ampicillin, are clustered in a unique 105,152-bp chromosomal region located at bp 4977946 (Fig. 1; and see Table S2 in the supplemental material). Within this chromosomal region, the resistance genes are located in the upstream 20%, within a

22,530-bp region that we named the "genomic resistance module" (GRM).

The UMN026 GRM encompasses 29 ORFs (25 complete and 4 partial), of which 8 are predicted to be associated with resistance to antimicrobial agents and 2 with resistance to antiseptics or heavy metals. Genes responsible for five of the six constituent resistance markers of the ACSSuTTp phenotype are present, including the chloramphenicol acetyltransferase gene, *cat*; the *dhfrVII* trimethoprim resistance gene, encoding a dihydrofolate reductase; the adenylyl transferase gene, *aadA*, conferring resistance to streptomycin; the sulfonamide resistance gene, *sulI*, encoding a dihydropteroate synthetase, and the *bla*<sub>TEM</sub> gene, encoding a penicillinase. Additionally, three genes belong to the *mph* cluster and encode a phosphotransferase that confers high-level resistance to erythromycin (MIC, >256 mg/liter [data not shown]). Likewise, two genes associated with resistance to antiseptics or heavy metals are present: the *ebr* gene, which confers ethidium bromide resistance; and a putative chromate transporter gene, which has been defined based on protein domains and could induce resistance to chromate (Fig. 2). This finding illustrates the importance of whole-genome sequencing in the elucidation of the genetic underpinnings of antimicrobial resistance, as previously reported for the plasmidic region in *E. coli* SMS-3-5, a multidrug-resistant environmental group D strain (4), and for the genomic island reported in an *Acinetobacter baumannii* strain (3).

The larger 105-kbp chromosomal region itself can be classified as a genomic island (2) based on the following four characteristics. First, the region's size is over 10 kbp. Second, although its overall G+C content does not vary statistically from the rest of the genome (50% versus 50.7%), its GC deviation (i.e., the mean GC content in a 1-kbp window – the overall mean GC) is frequently higher than 2 standard deviations (Fig. 1). Third, it is located next to a tRNA gene (*leuX*). Fourth, it includes mobility genes such as integrases, transposases, resolvases, and phage-like elements (Fig. 1; and see Table S2 in the supplemental material).

The GRM, located in the upstream part of this genomic island, is characterized by a high G+C content (55% versus 50.7% for the whole genome,  $P < 0.001$ , using a chi-square test). The GRM is flanked upstream by the *leuX* tRNA gene, and downstream by transposases of the IS1 family (Fig. 1B; and see Table S2 in the supplemental material). The GRM includes many of these mobility-associated genes. We observed two integrase genes: i.e., *intB*, a phage-like element gene, and *intI1*, which codes for the integrase of class 1 integrons. Moreover, 10 transposases or transposase fragments, including four IS26 and two IS1 copies, are present (Fig. 2; and see Table S2 in the supplemental material). In addition, we discovered the presence of a rearranged Tn21-like element, with the transposition region comprising *tnpA*, *tnpR*, and *tnpM*, the resolution site (*res*), and, downstream, a class 1 integron. The class 1 integron contained the integrase *intI1*, the *attI* site, and resistance gene cassettes *dhfrVII* and *aadA*. The last genes of the integron—i.e., *ebr*, *sulI*, and a fragment of ORF5 (which corresponded to the 3'-conserved segment)—are inverted. However, flanking inverted repeats (IRs), as usually observed around transposons and integrons, are partly present. That is, IR<sub>mp</sub> (which usually is localized in the upstream part of Tn21)

FIG. 1. Representation of the 105-kbp genomic island of *Escherichia coli* strain UMN026, bearing the GRM. (A) Circular representation of the *E. coli* UMN026 chromosome. From the center outward, the concentric circles display the following: (i) GC skew ( $G + C/G - C$  using a 1-kbp sliding window); (ii) locations of tRNAs and rRNAs (gray) and insertion sequences (dark gray); (iii) GC deviation (mean GC content in a 1-kbp window – overall mean GC), with gray areas indicating that the deviation is higher than 2 standard deviations; (iv) locations of the genomic islands corresponding to prophage regions (light gray), PAIs (dark gray), and the 105-kbp genomic island containing the 23-kbp GRM described in this study (black); and (v) scale, in which 1 graduation corresponds to 50 kbp. (B) Enlargement of the 105-kbp genomic island. The first and sixth lines represent the 2-kbp window scale. The second and fifth lines indicated the GC deviation and GC skew in a 1-kbp window. On the third and the fourth lines, genes annotated manually are indicated by arrows. Genes annotated with another *E. coli* genome serving as the reference genome are represented by rectangles. Insertion sequences are represented in dotted boxes. The *leuX* tRNA is indicated, as well as the transposases of the IS1 family and the *uxuA* gene (which flank the downstream part of the GRM and the genomic island, respectively). The plain box indicates the GRM.

is absent; only 30 of the 38 bp of *IR<sub>mer</sub>* (which usually is localized in the downstream part of Tn21) are present; and only *IR<sub>i</sub>* is found upstream of *intI1* in the class 1 integron, whereas *IR<sub>t</sub>*, which usually is localized in the downstream part of class 1 integrons, is missing (Fig. 2).

The Tn21-like element of the GRM is homologous to other Tn21-like elements described in strains of *Shigella flexneri* (GenBank accession no. AF188331 [no corresponding publication]) and *Aeromonas hydrophila* (14), in which a macrolide inactivation gene cluster and *bla<sub>TEM</sub>* are associated with the

Tn21-like element. However, the *tni* module and the *mer* operon, which occur in the above-described Tn21-like elements, are lacking in the Tn21-like element of the UMN026 GRM. The large number of transposases observed in this GRM could explain these rearrangements, which may have eliminated the mobility of the Tn21-like element by interruption or deletion of IRs. Additional elements involved in DNA mobilization, as well as the *intB* gene, flank the GRM, suggesting that the region has been intensively rearranged. This abundance of mobility elements may explain the observed chromo-

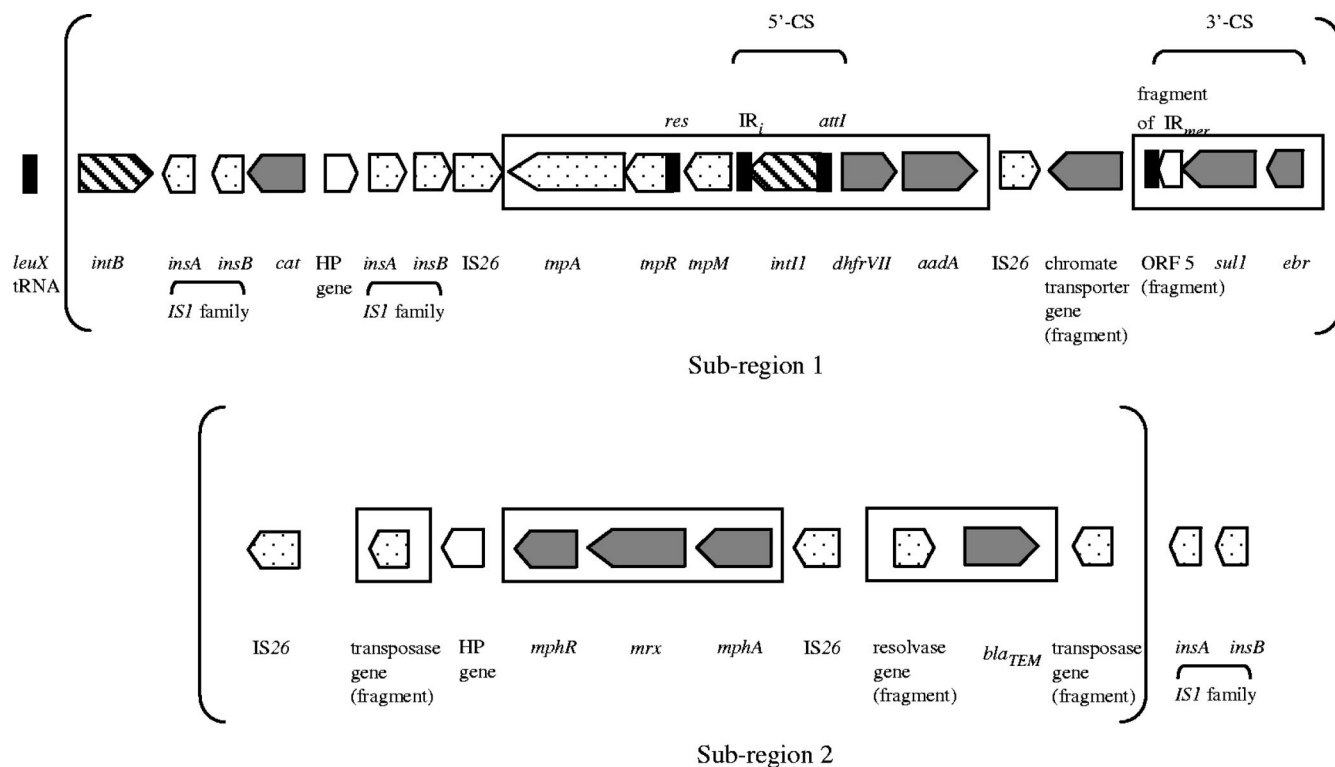

FIG. 2. Representation of the genes annotated in the *Escherichia coli* UMN026 GRM. ORF categories are indicated as follows. Genes coding for resistance to antibiotics, antiseptics, or heavy metals are in gray, transposition elements are dotted, integrases have diagonal lines, and a hypothetical protein (HP) is in white. Boxes indicate the rearranged Tn21-like element. The partly inverted repeats (IRs), as well as the *res* and *attI* sites of the Tn21-like element and of the class 1 integron, respectively, are indicated in black. The ORFs and noncoding sequences are not presented to scale. Subregions 1 and 2 are indicated within brackets (Fig. 4).

somal location of these resistance genes, which usually are found in plasmids. Indeed, to our knowledge, this represents the first report in *E. coli/Shigella* strains of a chromosomal location for *dhfrVII*, the *mph* cluster, a chromate resistance gene, and *bla<sub>TEM</sub>* (Fig. 1B and 2).

A search for the presence of these GRM genes in other organisms was performed with BLAST, using a criterion of nucleotide sequence similarities greater than 90%. Most of the GRM genes, i.e., 27 (93%), were present in other *E. coli/Shigella*, genomes, in either a plasmid or chromosomal location

(see Table S1 in the supplemental material). Additionally, 11 (38%) of the genes were shared with *E. coli* 042, a group D diarrheal disease isolate, in which they were localized elsewhere in the chromosome (Fig. 3). Hypotheses regarding the evolutionary history of UMN026 can be derived by noting that another strain bears, in a different chromosomal location, some genes of subregion 1 of the GRM (see Table S2 in the supplemental material). Indeed, *E. coli* 042, shares a part of the resistance phenotype of CGA, including resistance to chloramphenicol, streptomycin, sulfonamides, and tetracycline

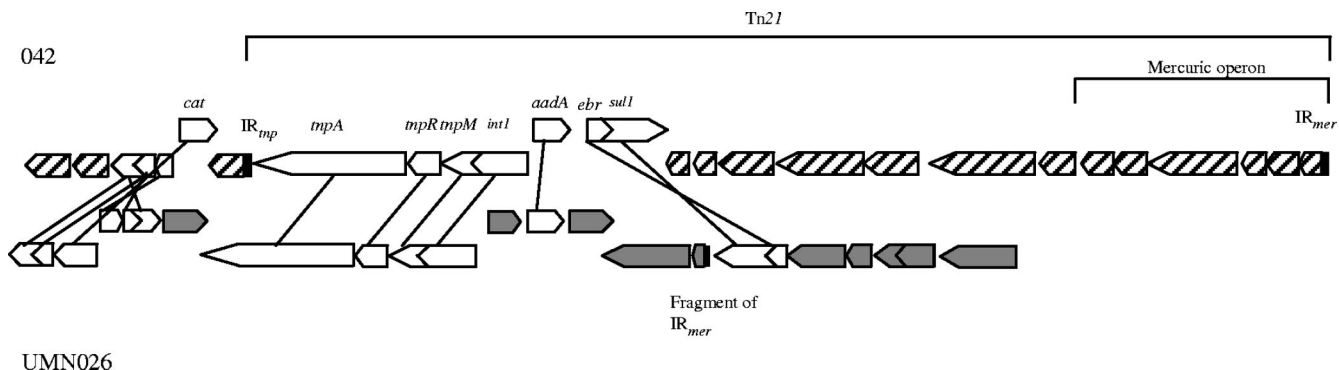

FIG. 3. Representation of the ORFs of the UMN026 genomic resistance module that are shared with *Escherichia coli* strain 042. In both strains, the corresponding regions are situated on the chromosome. Shared ORFs are indicated in white, whereas 042- and UMN026-specific ORFs are represented by diagonal lines and gray shading, respectively. IRs are represented in black.

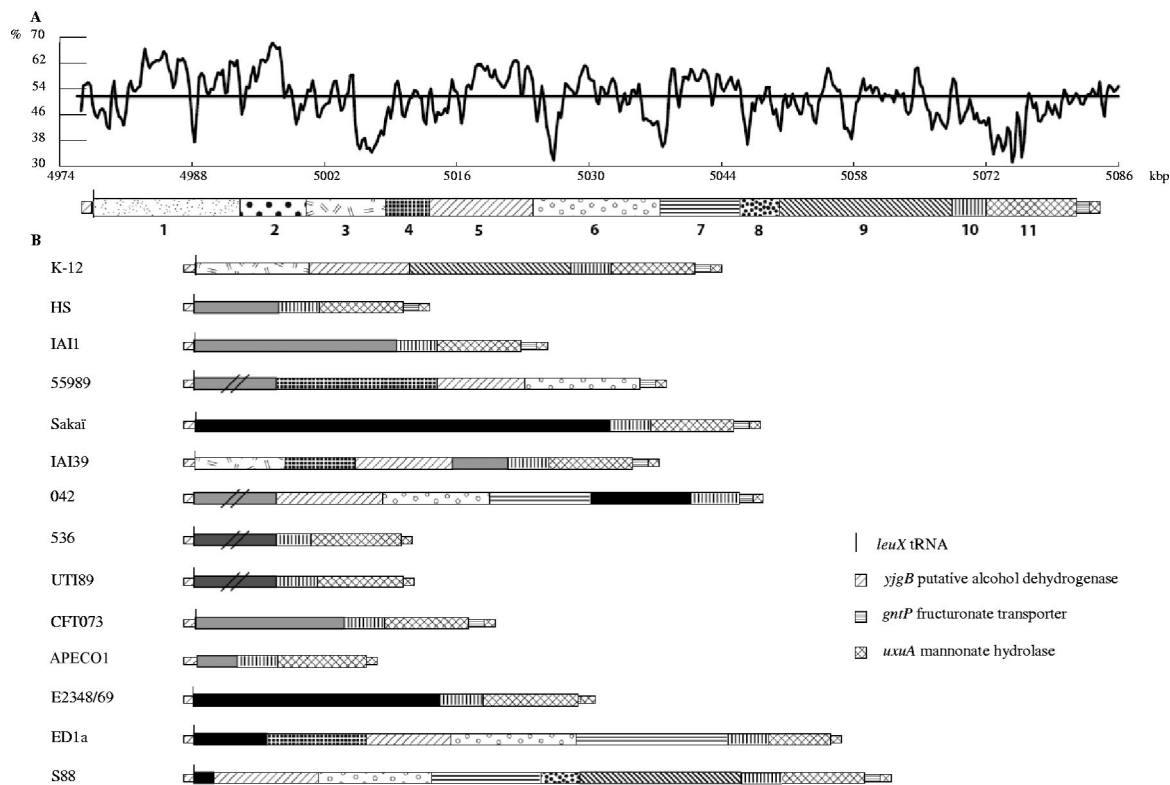

FIG. 4. Genomic islands at the *leuX* tRNA insertion hot spot in 15 *Escherichia coli* strains. This region was defined using the synteny breaks between 15 pathogenic and commensal *E. coli* strains from various phylogenetic groups, including CGA strain UMN026. In all of the *E. coli* strains, the gene just before the *leuX* tRNA gene corresponds to the ECK4262 gene (*yjgB*, coding for a putative alcohol dehydrogenase), whereas the beginning of the core genome immediately after the *leuX* tRNA gene corresponds to the ECK4313 gene (*uxuA*, coding for mannonate hydrolase). In strains APECO1 and 042, the *leuX* tRNA gene is absent. (A) The genomic island from UMN026, with its GC deviation (mean GC content in a 500-bp window – overall mean GC of complete genome [50.7%; indicated by the horizontal line]) is represented by the GC content (%) along the position in kbp (origin at the *thrA* gene). The organization of the various modules is also indicated along the genomic island. A total of 11 subregions (for which the complete list of genes and their functional descriptions are available in Table S2 in the supplemental material) have been defined, with the first and second of these corresponding to the GRM (Fig. 2) and the last to the *fim* operon (crossed lines). (B) Organization of the subregions in the 14 compared *E. coli* strains. Homologous subregions have the same geometric code. Black subregions are strain specific. Gray subregions are found in other strains but at another genomic location. (The ones containing double black slashes are not drawn to scale since they are much longer.) Dark gray subregions indicate PAI II in strains 536 and UTI89.

(i.e., CSSuT [data not shown]). All of the genes involved in this phenotype are present in strain 042, but clustered elsewhere in the chromosome within the complete Tn21 (Fig. 3). This suggests a possibility of multiple recent events of acquisition of this resistance phenotype in these two virulent, but pathotypically distinct, group D strains, indicating a selective pressure in their natural niche.

Despite the use of a fairly strict similarity criterion (i.e., 90% identity), we found 21 of the GRM genes (73%) in *Salmonella enterica*, 15 (52%) in other *Enterobacteriaceae*, 5 (17%) in *Haemophilus* spp., 2 (7%) in *Neisseria* spp., 1 (3%) in *Pasteurella* spp., 3 (10%) in *Corynebacterium* spp., 3 (10%) in *Streptococcus* spp., and 1 (3%) in *Staphylococcus aureus*. As for environmental species, 13 (45%) of the GRM genes were present in *Acinetobacter baumannii*, 7 (24%) in *Pseudomonas aeruginosa* or other *Pseudomonas* spp., 7 (23%) in *Aeromonas* spp. including *Aeromonas hydrophila*, 2 (6%) in *Achromobacter* spp., and 1 (3%) in *Stenotrophomonas maltophilia* (see Table S1 in the supplemental material). Finding of homolog genes in other, phylogenetically distant species suggests multiple hori-

zontal transfers allowed by the numerous mobility-associated genes described above.

We next compared the entire 105-kbp *leuX* tRNA genomic island of UMN026 to the sequences occurring at the same chromosomal location in 14 other sequenced *E. coli* genomes (Fig. 4). As previously reported (16), we find that the *leuX* tRNA region was a hot spot of insertion. The *E. coli* genomic regions inserted at the *leuX* tRNA have a composite structure; indeed, a total of 11 subregions were defined, the first and second of which corresponded to the UMN026 GRM (Fig. 2). The composition of these subregions (i.e., a listing of the constituent genes with their functional descriptions) is available in Table S2 in the supplemental material. The presence/absence in different strains of specific subregions is uncorrelated by eye either to phylogenetic group or pathotype (Fig. 4). For example, parts of the KpLE2 phage-like element (i.e., subregions 3, 5, and 9 [Fig. 4; and see Table S2 in the supplemental material]) are present in the commensal-derived laboratory strain K-12, from phylogenetic group A, but are not found in commensal strains HS and IAI1, from phylogenetic groups A and

B1, respectively. Likewise, two other subregions—i.e., regions 10 (which contains hypothetical proteins and *N*-acetylneuraminic acid outer membrane channel protein) and 11 (which encompasses the *fim* operon coding for fimbrial proteins)—are found at this insertion point in all analyzed *E. coli* strains, except for the enteroaggregative *E. coli* strains 55989 (group B1) and 042 (group D). Moreover, apart from the GRM region, the organization of the genomic island subregions in UMN026 (group D, pathogenic) is similar to that of phylogenetic group B2 strains S88 and ED1a, which are pathogenic (newborn meningitis) and commensal strains, respectively. Interestingly, at the same position downstream of *leuX* tRNA and *intB*, in strains UTI89 and 536, which are two group B2 strains associated with UTI, pathogenicity island II (PAI II) is present (Fig. 4). PAI II comprises such virulence-associated genes as *hek* and the *pap* operon (which contribute to adherence); *hly* (which lyses erythrocytes and impairs phagocyte function); and, in strain UTI89, *cnf1* (which is cytotoxic for epithelial cells). Furthermore, the *leuX* tRNA region has been demonstrated to be involved in the virulence attenuation of asymptomatic bacteriuria strains (18). Indeed, in some asymptomatic bacteriuria strains, the end of the *leuX* tRNA genomic island encompassing the *fim* operon is lacking or exhibits point mutations that inactivate the *fim* operon, which is known to be involved in adherence (18). These observations underscore the importance of the *leuX* tRNA-associated region in the plasticity of the genome by modulating the acquisition and loss of genes of virulence or resistance.

UMN026 was selected as the representative CGA strain for genome sequencing (16) because of its typical CGA-associated O17 antigen, virulence profile, and ACSSuTTP resistance profile. To clarify the generalizability of the present findings, it will be useful in the future to assess how broadly distributed the UMN026 GRM is within CGA, as well as within non-CGA lineages that are closely related (e.g., ST394) or more distantly related (e.g., the O15:K52:H1 clonal group) (9) to CGA, including isolates with resistance profiles similar or dissimilar to that of UMN026. Likewise, in view of previous evidence that the ACSSuTTP phenotype of certain CGA and O15:K52:H1 strains is conjugally transferable to laboratory strains (6, 10), it will be relevant to assess possible conjugal transfer of the GRM.

In summary, annotation of the whole-genome sequence of strain UMN026 allowed us to define the genetic underpinnings of this strain's antimicrobial resistance. Most of the responsible genes were clustered within a unique 23-kbp chromosomal region, named the GRM, which occurred within a 105-kbp genomic island situated at the *leuX* tRNA locus. Comparative genome analysis showed that this genomic island is located at a hot spot of gene acquisition and loss within the chromosome. This illustrates the plasticity of *E. coli* genomes, which supports multiple adaptive paths (16) that allow, at a single locus, the alternative presence of resistance or virulence genes (1, 5, 11).
